Introduction

Every family of stories has its contrarian, and the story of modern astronomy had Fred Hoyle. For more than half a century, from the 1930s to the end of the century, the Yorkshire-born theorist was one of the science's sharpest minds and, famously, one of its most stubborn: the co-creator of the theory of how stars forge the chemical elements, the co-inventor of the steady state cosmology that ruled the field for a generation before losing to its rival, the writer who gave the universe its Big Bang name as a term of ridicule, the popular author and broadcaster who did as much as anyone to teach the postwar public its astronomy, and the late-career controversialist whose scientific radicalism drifted past the field's patience.

The book in the reader's hands tells his story the series' way: the life, the science, the discoveries, the context, the legacy, and the honest accounting of a great scientist who was wrong about the biggest question of all, and right about nearly everything else that mattered.

Hoyle's career rewards the biography-first treatment this series gives its astronomers, because the science and the personality were inseparable. His theory of stellar nucleosynthesis, the demonstration that the elements of the periodic table are cooked in stars, was a triumph of the theorist's trade, built on nuclear physics applied with audacity; his steady state theory, the cosmology he defended for decades against the gathering evidence, was the same audacity pointed the wrong way; and the two episodes, the triumph and the defeat, were worked by the same mind, in the same style, in the same decade. The life's lesson is the series' own favorite theme, that science is a human practice whose instruments are minds, and that the minds' virtues and vices travel together.

The chapters that follow trace the standard arc: the discovery of the person, the understanding of his character and method, the science behind his work in plain terms, the observation and measurement campaigns he shaped, his features as a scientist, his context among his contemporaries, the modern understanding of his contributions, the research programs he opened, his significant discoveries, the challenges and mysteries that marked his career, the future of the work he began, the lighter trivia file, and the conclusion of his significance. The reader who wants the executive summary before the chapters start holds it in two sentences: Fred Hoyle was among the finest theoretical astrophysicists of the twentieth century, and the science's mainstream spent fifty years arguing with him, sometimes gratefully, sometimes not, and the argument made the science better in both directions.

The childhood chapter deserves one more note, the science's presence in the

village. The boy's first astronomy, by the memoirists' account, was the sky itself, the village dark, the schoolbooks, and the practical astronomy of the era's wartime skywatching, and the note matters because the series' biographies keep finding their subjects in the child: the mathematics loved early, the sky noticed early, and the region's culture of plain practical cleverness, the one the county is proud of, formed before the university refined. The discovery chapter's last note is that the person was made twice, once by Yorkshire and once by Cambridge, and both makings held to the end.

The final discovery-chapter note is the iconography, the person's presence in the field's image bank. The photographs the era's records keep are the ones the reader can check: the tousled, cheerful theorist at the blackboard, the broadcaster at the studio microphone, the elder statesman of the hillside decades, and the images' sum is the public person the biography has described, the plain Yorkshire physicist the century watched think; the note's last item is the contrast the biographers draw between the public warmth of the photographs and the private guardedness of the person, the gap the mysteries chapter keeps, and the discovery chapter files the images with the rest of the evidence.

The wool town's gift opens the account, because the life's first physics was provincial. The Yorkshire childhood: the cloth merchant's son, the village school, the sky watched from the moor's edge, the boy's astronomy self-taught from library books before any formal training; the introduction keeps the origin as more than color: the life's contrarian confidence was bred in the provincial distance from the capitals' consensus, the theorist who trusted his own arithmetic arriving that way early, and the frame's meaning: the reader should hold the Bingley boy beside the Cambridge professor throughout, the two being the same person at different addresses, the introduction promising the full arc: the moor's edge to the world's argument, one unbroken temperament.

The broadcaster's fame comes second in the opening, because the theorist was also the era's public voice. The radio talks of the postwar years: the Yorkshire accent explaining the stars to the nation, the series of broadcasts that gave the public its cosmology, the phrase that stuck and named the rival theory forever; the introduction keeps the dual career plainly: the scientist sold half a million books of popular science in an era when such a thing was rare, the fame being earned twice, in the journals and on the airwaves; and the meaning for the reader: this volume's subject was one of the first scientists the public knew personally, the contrarian being also the field's

ambassador, the broadcasts and the papers being one career conducted in two languages.

Chapter 1: The Discovery of Fred Hoyle

The person the series names in this volume was discovered twice, in the standard sense the biography chapter uses: once by his own generation, which watched the Yorkshire mathematician become the Cambridge theorist, and once by history, which has spent the decades since his death settling his account.

His generation's discovery came early, and its stages are the standard ones of the era's British science. He was born in 1915 in the West Riding of Yorkshire, a village childhood of modest means, and his gift for mathematics carried him through the local schools to Cambridge, the era's standard ladder for a Yorkshire talent; the university's mathematics tripos made him a wrangler, the culture's honorific for the top-ranked, and the theoretical culture of 1930s Cambridge, the one this series' Eddington volume describes, took him in. The war interrupted the ladder as it interrupted everything, and the war's radar work, the shared experience of a whole generation of radio scientists, gave him the applied physics apprenticeship that the peacetime theory would build on.

The postwar discovery was swift, and its stages were the theory's. His 1946 paper on the synthesis of the elements opened the problem his greatest work would solve; the steady state theory of 1948, co-authored with two younger collaborators, made him the public face of a cosmology; the 1950s' nucleosynthesis campaign, the collaborative traversal of the periodic table with three co-authors, produced the field's landmark; and the decade's end found him in the field's first rank, a professor, a broadcaster, and a scientific celebrity, the Yorkshire accent on the BBC teaching the nation the stars. The discovery's stages are the chapters' subjects in order, and the biography's note here is the arc's shape: the outsider who arrived, conquered, and then, characteristically, refused to leave the field's arguments on the field's terms.

The history's discovery, the second one, is the continuing process the later chapters describe: the rehabilitation of the nucleosynthesis work as one of the century's scientific masterpieces, the honest reassessment of the steady state campaign as a wrong theory defended brilliantly, the archival scholarship on his popularizing and institutional work, and the field's slow settling of his account, an account with real credits, real debits, and a personality that guarantees the auditors will never be bored. The person the reader meets in these pages was discovered by his generation as a genius, and by ours as something more human and more interesting: the contrarian who earned his arguments.

The chapter's last understanding note is the person's own account of himself,

the autobiographical record. The memoirs and the interviews the person left, read against the colleagues' testimony, give the understanding its final check, and the check's result is the sketch's confirmation: the plain self-telling, the physical self-explanation, the scores settled publicly and the losses reframed; the understanding the reader should take is the record's whole one, the person's own voice joined to the field's account of him, and the differences between the two, where they differ, are the biography's own field notes. The understanding chapter closes with the series' standard rule: the self-told life and the field-told life are both evidence, and the reader's understanding holds them together.

One more discovery note, the era's founding generation the person joined. The postwar theoretical astrophysics' founders, the names the field's textbooks carry, were the person's cohort and in several cases his collaborators, and the discovery chapter's honest setting is the group: the problems shared, the schools competing, the conferences' arguments, and the group portrait the field's history paints of the era when the subject was invented; the person's place in the portrait is the loud Yorkshire one, the contrarian at the center of the era's two biggest arguments, and the discovery of him is inseparable from the discovery of the group. The chapter's last note is the group's fate, the members' honors and their disputes, the field they built outliving all of them, and the portrait's meaning: the science's founders are a generation, not a genius alone.

The war's interlude gets its paragraph, because the theorist's formation had a uniformed gap. The conflict years: the mathematician drafted into the electronics of detection, the radar teams of the naval war, the skills of radio and signal sharpened alongside the era's other future astronomers; the chapter's honest placement: the interlude broke the academic decade and built the profession's network, the war's laboratories being the mid-century's strangest graduate school; and the addition's meaning: the theorist returned to the peace with the tools and the colleagues of the electronic era, his later openness to the radio evidence owing something to the war's apprenticeship, the discovery chapter keeping the uniformed years as the life's hinge: the abstract mathematician becoming the era's connected physicist.

The scholarships' ladder completes the discovery, because the provincial boy climbed by examination. The

competitive schools of the northern system: the scholarships won, the Cambridge college entered, the wool town's son arriving at the establishment's table by merit alone in an era when the table was mostly inherited; the chapter's honest scale: the climb was unusual and it mattered, the theorist's

later independence being partly the outsider's armor, the honors and the slights both received with the provincial's clear eye; and the discovery's closing note: the life's first discovery was the system's own: the mathematics competitions finding the moor's boy and moving him, the ladder working exactly as designed, the theorist being its product and, later, one of its severest critics.
