Introduction

Look up on a clear dark night and the stars come in groups. The mind does it without being asked: two here, three there, a long straggle there, the patterns jumping out the way faces do in clouds. Every culture that ever watched the sky saw figures in it, named them, told stories about them, and used them as calendar, compass, and scripture. The constellations are the sky's oldest maps, and this book is about how those patterns became the modern sky's official geography: eighty-eight regions with agreed names and drawn borders, the address system that every astronomer uses today.

The journey runs from the first Ice Age watchers who saw a hunter in the winter stars, through the Babylonian sky-watchers whose figures the Greeks inherited, through Ptolemy's catalogue of forty-eight, through the age of exploration when European navigators filled in the blank southern sky, to the 1920s when the International Astronomical Union swept up centuries of messy naming and fixed the eighty-eight we use now. Along the way the book explains what a constellation physically is, and is not: the stars of a figure are almost never a family, merely a line-of-sight partnership, and the shapes themselves are doomed, slowly, by the stars' own motions.

The book's route is the series' own: the history of the figures, the modern region definition, the set's characteristics, the physics behind the patterns, the observing craft on both the backyard and professional sides, a tour of the showcase figures, the world's other sky cultures, the modern address system at work, the research that still runs on the regions, the landmark discoveries attached to them, the open questions, the future of the sky's geography, the trivia, and the significance at the end. What carries the whole story is the fact that makes constellations unlike any other subject in this series: they are not objects at all but agreements, human convention laid on the sky, and the history of the convention is the history of astronomy's organizing mind.

Chapter 1: The Discovery of Constellations

The discovery of the constellations is really three discoveries: the noticing, thousands of years before writing; the standardizing, in the ancient Near East and Greece; and the fixing, in the twentieth century. Each has its own record, and the chapter tells them in order.

The noticing is prehistoric and must be read from its surviving works. The appearance of familiar figures at fixed seasons was the first calendar, and the deep past's monuments and stories encode the associations: the hunter of the winter sky, the bear of the north, the bull of the spring, the patterns' rising times tied to the year's work. The oldest direct evidence is interpretive but strong, the fact that pattern-making is universal: every culture with a sky tradition has groupings, and the correspondences across oceans, the seven-star cluster's worldwide fame as a calendrical object, the Pleiades' own volume tells that story, show how old and how practical the noticing was. The constellations were discovered the way fire was: everywhere, early, and by everyone.

The standardizing is the literate story. Babylon's sky-watchers, this series' Mesopotamia volume tells it, had organized the zodiacal band and the equatorial path through the stars by the early first millennium BC, and their figures, the bull, the lion, the scorpion, names the whole world still uses, entered the Greek world through the Hellenistic bridge. The Greek poets and astronomers built the inherited figures into a coherent sky: Aratus' Phaenomena, a poem of the sky's figures and their risings, was the ancient world's most-copied astronomy work, and its source, Eudoxus' treatise, already treated the figures as a fixed standard. The Greek figures' own biographies deserve the standardizing's note, the myths' arrival. The inherited Babylonian figures took their lasting shapes in the Greek telling: the hunter and the scorpion placed opposite as the enemies of the story, the rescue of the princess, the labors' animals scattered along the zodiac, the myths of the era's poets becoming the sky's fixed furniture, and the figures' arrangements, the scorpion chasing the hunter, the bear circling the pole, encode the stories in the geometry. The mythological layer is what made the figures memorable: a sky of gods and monsters is a sky you can recite, and the recitability, the schoolbook of Aratus and the countless retellings, is why the Greek set survived when the Babylonian originals were forgotten, the inheritance outliving the originators.
The standardizing's monument is Ptolemy's Almagest, the second-century catalogue that fixed forty-eight figures with their member stars and their positions, the sky's first official map, and Ptolemy's forty-eight remained the classical set for fourteen centuries: the northern sky's figures, visible from Alexandria, were now canonical, and the Greek names, Latinized, became the permanent standard.

The filling-in and the fixing complete the discovery. The southern sky, invisible from the classical latitudes, stayed unnamed by Europe until the age of sail: the Dutch navigators Keyser and de Houtman charted a dozen southern

figures from their voyages at the century's turn, figures the cartographer Plancius set on globes, exotic birds and southern fish where the old sky ended; Lacaille's own expedition deserves the filling-in's paragraph, the surveyor's record. Nicolas-Louis de Lacaille, the French astronomer, spent 1751 to 1753 at the Cape of Good Hope, the first professional survey of the southern skies, cataloguing nearly ten thousand stars and charting the regions the classical world never saw; his fourteen new figures, published posthumously in his southern star map, named the Enlightenment's instruments, the telescope, the microscope, the clock, the furnace, the level, the chemical apparatus, the sky's laboratory, and his splitting of the ancient ship, Argo Navis, into its workable parts began the obsoleting that the IAU would finish. The expedition's meaning for the set: the southern sky is the eighteenth century's contribution, the era's science writing its own tools into the sky's permanent furniture, the address system's most recent major renovation.
Lacaille, observing from the Cape in the 1750s, added the telescope-era's fourteen, the instrument figures of the southern sky; and the cartographers of the following century, Bayer and Bode among them, spread the growing set across ever-finer globes. The mess had grown, and the fixing came in two steps: in 1922 the International Astronomical Union adopted an official list of eighty-eight names and their three-letter abbreviations, and in 1930, from the work of Eugene Delporte, it published the boundaries, drawn along fixed lines of the 1875 coordinates, that give every point of the sky exactly one constellation address. The 1922 and 1930 steps deserve the fixing's own paragraph, the settlement's procedure. The IAU, founded in 1919 as the world's astronomers' union, took the sky's chaos as an early agenda: the 1922 assembly adopted the eighty-eight names and the abbreviations, the committee's work sweeping away the last variant spellings and the contested figures; the boundaries took longer, Eugene Delporte, the Belgian astronomer, drawing the region edges along the 1875 epoch's coordinate arcs, star by star the charts, and the 1930 publication, the Atlas Celeste, fixed the result, the sky's whole surface divided once and forever. The settlement's discipline is worth noting: the drawers chose the 1875 grid deliberately, the epoch before the modern confusion, and the boundaries' simple rule, arcs of one coordinate between turning points, made the map checkable and permanent, the standard's engineering as careful as its diplomacy.
The discovery of the constellations, seen whole, is thus the story of the sky's organization: noticed by everyone, standardized by the ancients, filled by the navigators, and fixed by the moderns, in that order, and the next chapter explains what the fixed thing actually is.

The Chinese standard deserves the discovery chapter's own paragraph, because the sky's other great tradition was standardized as thoroughly as the Greek, and independently. The Chinese astronomers organized the celestial sphere their own way: a system of some two hundred and eighty small lunar mansions and enclosed figures, the sky read as a celestial bureaucracy, the stars' names drawn from the emperor's court, the celestial empire mirroring the earthly one, the whole scheme anchored to the pole and the equator rather than the ecliptic; the system's star maps survive in charts and catalogues older than Europe's printed ones, the tradition running unbroken for two millennia. The takeaway for the whole subject: the eighty-eight the book describes are one civilization's settlement, and the Chinese sky, its figures still studied by name in the historical literature, proves that the standardizing was a universal instinct rather than a Greek invention, the sky inviting organization the way rivers invite bridges.

The gap-fillers deserve the standardizing's second note, the seventeenth century's modest additions. Between Ptolemy's classical forty-eight and Lacaille's southern instruments, the Polish astronomer Hevelius, the century's last great naked-eye observer, charted the northern sky's faint stretches and filled the gaps with seven new figures, the lynx, the sextant, the fox, the little lion, the little triangle, the shield he named for his king, and the hunting dogs he loosed beside the bear; the additions were modest by design, the observer admitting that the lynx's stars were so faint that lynx-eyed observers were needed to see them, the figure's name being the joke's own explanation. The card is the set's middle growth: the northern sky was already crowded, the gap-filling era adding small figures among the giants, the seventeenth-century names still on the modern list, the modesty of the additions being the era's honesty, the sky's good names already taken.

The Arabic bridge deserves the standardizing's third note, the star names' own immigration. The Greek figures passed through the Arabic-speaking world's centuries of preservation and observation, and the star names the modern sky uses came back across the bridge with them: the follower, the dove, the flying one, the swan's tail, the words Arabic on their faces and unremarked in every modern sky-gazing guide, the astronomers of the Arabic tradition having measured and named the figures' individual stars with a care Europe did not match again for centuries; the inheritance's depth is the working sky's daily vocabulary, the brightest stars of the northern winter all bearing the tradition's names. The card is the transmission's honesty: the constellations' figures are Greek and the figures' stars largely Arabic, the sky-map being a palimpsest of the cultures that kept it, the standard that reached

1922 having been carried, century by century, by whoever was doing the astronomy.
